**Drought, Mutualism Breakdown, and Landscape-Scale Degradation of Seagrass Beds**

**Graphical Abstract**

**Highlights**

- Climate extremes may cause breakdown of the facultative seagrass-lucinid mutualism
- Loss of this mutualistic feedback can amplify seagrass ecosystem degradation
- Risk of marine mutualism breakdown goes beyond the well-known obligate coral symbiosis
- These mechanisms need inclusion in marine conservation and restoration approaches

**In Brief**

Concerns grow that disruption of mutualisms may amplify marine ecosystem degradation. de Fouw et al. show how drought triggered the breakdown of a facultative mutualism that accelerated landscape-scale intertidal seagrass collapse, revealing a hidden risk of mutualism dependency in marine ecosystems beyond the well-known obligate coral symbiosis.

SUMMARY

In many marine ecosystems, biodiversity critically depends on foundation species such as corals and seagrasses that engage in mutualistic interactions [1–3]. Concerns grow that environmental disruption of marine mutualisms exacerbates ecosystem degradation, with breakdown of the obligate coral mutualism (“coral bleaching”) being an iconic example [2, 4, 5]. However, as these mutualisms are mostly facultative rather than obligate, it remains unclear whether mutualism breakdown is a common risk in marine ecosystems, and thus a potential accelerator of ecosystem degradation. Here, we provide evidence that drought triggered landscape-scale seagrass degradation and show the consequent failure of a facultative mutualistic feedback between seagrass and sulfide-consuming lucinid bivalves that in turn appeared to exacerbate the observed collapse. Local climate and remote sensing analyses revealed seagrass collapse after a summer with intense low-tide drought stress. Potential analysis—a novel approach to detect feedback-mediated state shifts—revealed two attractors (healthy and degraded states) during the collapse, suggesting that the drought disrupted internal feedbacks to cause abrupt, patch-wise degradation. Field measurements comparing degraded patches that were healthy before the collapse with patches that remained healthy demonstrated that bivalves declined dramatically in degrading patches with associated high sediment sulfide concentrations, confirming the breakdown of the mutualistic seagrass-lucinid feedback. Our findings indicate that drought triggered mutualism breakdown, resulting in toxic sulfide concentrations that aggravated seagrass degradation. We conclude that external disturbances can cause sudden breakdown of facultative marine mutualistic feedbacks. As this may amplify ecosystem degradation, we suggest including mutualisms in marine conservation and restoration approaches.

RESULTS

Mutualisms are important drivers of global biodiversity and ecosystem functioning, as many organisms are directly involved in networks of beneficial interactions [4, 6, 7]. A vast majority of terrestrial plants depends on mutualistic partnerships [6, 7], and in marine ecosystems, ecosystem-structuring foundation species such as corals, kelp, salt marsh plants, mangroves, and seagrasses may depend on them to decrease physical stress or gain resources [1–3]. Mounting evidence suggests that global change can disrupt such mutualistic feedback loops [2, 4, 8, 9], potentially accelerating habitat degradation [1, 2, 4]. Coral-bleaching events (i.e., expulsion of endosymbiotic algae) are an iconic example of environmental changes (e.g., global warming) leading to the breakdown of an obligate mutualism and ecosystem degradation [2, 5]. Similar to coral reefs, many other marine ecosystems shaped by mutualism-dependent foundation species also exhibit sudden and large-scale declines [10, 11]. However, in contrast to the obligate coral symbiosis, the mutualisms in these ecosystems are facultative [1] and can vary in strength depending on prevailing conditions [3]. Therefore, it remains unclear whether mutualism breakdown due to environmental change is a general risk inherent to mutualism-dependent marine ecosystems.

Here we investigate the hypotheses that (1) similar to the obligate coral symbiosis, climatic extremes can trigger sudden breakdown of a facultative mutualism between seagrass and
sulfide-consuming lucinid bivalves, and (2) the loss of this self-sustaining mutualistic feedback has the potential to exacerbate seagrass ecosystem degradation. Seagrass beds are essential for coastal zones worldwide because they provide coastal protection, act as carbon and nutrient sinks, and serve as vital habitat for many species [12–14]. Seagrass ecosystems are currently degrading at an accelerating rate worldwide [13], and losses are often typified by sudden die-off. Such rapid declines have been attributed to climatic extremes such as storms, high seawater temperatures, and low-tide desiccation events in intertidal beds [12, 15–18], but also to the disruption of internal feedback mechanisms by environmental changes [11, 19]. Seagrass meadows increase water clarity by trapping suspended particles and stabilizing sediments, thereby facilitating their own growth [3, 11, 14]. This positive feedback, however, also results in a negative feedback as organic matter accumulates in the sediment, and its anaerobic decomposition involving sulfate-reducing bacteria yields toxic sulfide [3, 20, 21]. To prevent sulfide accumulation, seagrasses can engage a (recently discovered) mutualistic feedback loop with lucinid bivalves and their gill-inhabiting, sulfide-oxidizing bacteria [3, 12]. In return, the bivalves and their endosymbionts profit not only from sulfide that is indirectly provided by the seagrasses, but also from oxygen released by seagrass roots [3, 22, 23].

To investigate our hypotheses, we studied a landscape-scale die-off event in the intertidal seagrass beds of Banc d’Arguin—a pristine Marine Protected Area in Mauritania (West Africa). In this tropical Sahara Desert climate, low-tide desiccation is a common stressor for seagrasses [24], but in 2010 and 2011 the region experienced exceptional drought and heat (with anomalies of +2°C to +3.5°C compared to long-term mean monthly temperatures) [25–27]. Using local climate data and remote sensing analyses of spatiotemporal seagrass dynamics, we investigated whether (1) the die-off could be related to low-tide desiccation stress caused by heat, wind, and/or drought extremes and (2) disruption of a feedback was an important accelerant of the observed decline. Finally, we carried out field measurements to examine the potential link between desiccation, seagrass die-off, and breakage of the mutualistic feedback.

**Local Climate Analyses**

Analyses of data from the nearest weather station suggest that in our study area, the summer of 2011 was exceptionally warm, windy, and dry, leading to a high evaporative demand (Supplemental Experimental Procedures). The number of extreme days in the warmest three months (August–October)—defined as days over the 95% percentile—was higher for all four variables included in our analyses (Figure 1). The number of recorded extremely hot and windy days in the warmest months was at least 1.3 times higher in 2011 compared to other years. More importantly, however, the number of extremes in the two most direct proxies of evaporation, and thus low-tide desiccation stress—dew point depression and water vapor pressure deficit [28]—was over five times higher in 2011.

**Remote Sensing and Potential Analyses**

To investigate spatiotemporal seagrass cover changes, we calculated the normalized difference vegetation index (NDVI) from Landsat imagery taken in 2007, 2009, 2011, and 2013 and combined these analyses with ground observations (Supplemental Experimental Procedures; Figure S1). NDVI data indicate that degradation of the intertidal seagrass beds was initiated in 2011. After a small increase between 2007 and 2009, NDVI started to decrease, after which a system-wide 44% decline occurred in 2011–2013 (Figures 2A–2E). This landscape-scale NDVI decrease was supported by ground observations that showed a 50% decrease in seagrass cover between 2009 and 2013 (Figure 2F).

Next, we used potential analyses to test whether disruption of internal feedbacks by, for instance, the drought contributed to the sudden seagrass collapse. This analysis fits a probability density function to a state variable per interval along an environmental stress gradient. Potential analysis is based on the fact that if distinct ecosystem states exist due to the presence of strong internal feedbacks, transitions between these feedback-stabilized states or “attractors” will occur rapidly because intermediate states are inherently unstable [29]. As a consequence, multimodality in a fitted probability density function (i.e., multiple peaks in occurrence) indicates multiple attractors: maxima in occurrence are identified as attractors, and minima as transition thresholds (or “repellors”) between attractors (Supplemental Experimental Procedures) [30–32]. For our analysis, we estimated a probability density function from NDVI data per 0.1-m interval along the drought stress gradient approximated by elevation (i.e., exposure time).

In line with climate and NDVI analyses, potential analysis shows that seagrass degradation was most likely initiated by desiccation in 2011. The analysis also identified two distinct ecosystem states of high and low NDVI, indicating that the collapse was not simply the result of external environmental forcing, but that shifts between the two states were mediated by internal feedbacks (Figure 3). For 2007 and 2009, the analysis...
identified only high-NDVI attractors (i.e., high seagrass cover) at elevations below mean water level (MWL) and low-NDVI attractors (i.e., low seagrass cover) above MWL. In contrast, near the end of the drought in 2011, when the system was collapsing, the analysis revealed two distinct attractors at intermediate elevations (−0.4 to 0 m MWL), indicating that areas with a high seagrass cover were propelled into an alternative, degraded state. In 2013, only the lower attractor was stable above −0.4 m MWL, implying that most areas at intermediate elevations had transitioned from a high seagrass cover state to a degraded state.

Field Measurements
The intertidal at Banc d’Arguin is dominated by the seagrass *Zostera noltii* that accumulates large amounts of silty, organic-matter-rich sediment of up to 24 m thick [33]. Characteristic for intertidal mudflats in general, the morphology throughout the area is typified by gently sloping terrain with shallow overlying relief (<10 cm; spatial scale: 10–50 m; Figure S2), resulting from sediment trapping by seagrass in interaction with morphodynamics driven by waves, tidal currents, and low-tide dewatering dynamics [11,34,35]. Because the die-off was patchy in nature, we first compared the characteristics of degraded patches with adjacent healthy patches at eight sites (four replicates per site) throughout our study area (Supplemental Experimental Procedures; Figure S1). Height measurements demonstrated that degraded patches were on average situated 6.7 cm higher than healthy areas (Figure 4A). Moreover, at low tide, we found that degraded patches were typically dry, with only 6% of the patches covered with a thin water film. In contrast, water drainage from higher toward lower patches resulted in the presence of a thin water film on the sediment surface at 88% of the healthy areas (Figure 4B). Apart from height and water, we detected no significant differences in general characteristics as indicated by sediment organic matter content (11.9% ± 0.4%; mean ± SE) and median grain size (70.0 ± 1.5 μm).

Detailed investigations of the benthic community revealed that, since the onset of degradation and our survey in 2012, aboveground seagrass biomass in degraded patches had been reduced by 89% (healthy: 124.3 ± 21.0 g dry weight per m²; degraded: 13.9 ± 6.9 g). Densities of the small (~1 cm) dominant lucinid bivalve *Loripes lucinalis* were nine times lower in degraded patches (Figure 4C), while sulfide concentrations in the sediment pore water were over four times higher and showed an increase with depth (Figure 4D). Finally, a comparison of patches sampled both before (2009) and after the collapse (2013) confirmed that lucinids declined dramatically (four to five times) in degrading patches while remaining stable in healthy patches (Figure S3).

DISCUSSION
Our findings of feedback-mediated seagrass decline, combined with low lucinid numbers and high sulfide levels following the 2011 drought, provide evidence that this climatic event initiated the sudden failure of a facultative mutualism that in turn exacerbated the observed collapse. Local climate data combined with NDVI and potential analyses suggest that seagrass degradation was initially triggered by dessication induced by high evapotranspiration (evaporation plus plant transpiration) during drought. After the onset, however, the decline persisted in the
Observed local sedimentation differences [11, 34, 35], making interaction with morphodynamics probably resulted in the collapse of seagrass itself: variations in shoot densities in higher patches more vulnerable to drainage and drought stress. Overall, drought stress is therefore increased in frequency and severity with global warming [36].

Extremes such as drought, strong winds, and tidal extremes are all predicted to increase in frequency and severity with global warming [36]. Although sea level rise could be expected to mitigate future drought events, expected increases in tidal amplitudes and heat waves can cause severe desiccation events, particularly when coinciding with strong winds and neap tides causing prolonged low-tide exposure [15, 24]. Extreme events such as drought, strong winds, and tidal extremes are all predicted to increase in frequency and severity with global warming [36].

Apart from desiccation, there are many other stressors for seagrass beds worldwide that could initiate breakdown of this mutualism, many of which are anthropogenic in origin [13, 39]. For example, eutrophication typically reduces light availability (and thus photosynthesis-driven oxygen release from seagrass roots) due to the higher competitive strength of algae [40], while accumulation to levels that are known to seriously hamper growth and survival of seagrass in general [20], and in our case to levels twice as high as those previously reported to decrease Z. noltii biomass by 30% [3].

Our study, combined with earlier work, highlights the importance of indirect responses of ecosystems to droughts [10]. Desiccation is a well-known stressor in subtropical to tropical intertidal seagrass beds such as Banc d’Arguin where drought and heat waves can cause severe desiccation events, particularly when coinciding with strong winds and neap tides causing prolonged low-tide exposure [15, 24].

Our study, combined with earlier work, highlights the importance of indirect responses of ecosystems to droughts [10]. Desiccation is a well-known stressor in subtropical to tropical intertidal seagrass beds such as Banc d’Arguin where drought and heat waves can cause severe desiccation events, particularly when coinciding with strong winds and neap tides causing prolonged low-tide exposure [15, 24].

Figure 3. Potential Analyses on NDVI across Elevation from 2007 to 2013

Dark and light shades depict NDVI ranges of high and low occurrence, respectively; closed and open markers depict “attractors” (peaks in occurrence) and “repellors” (lows in occurrence) that are automatically identified by the analysis per 0.1-m elevation interval. In 2007 (A) and 2009 (B), the analysis identified only a single high-NDVI attractor (+0.2) at low elevations and a low-NDVI attractor (−0.1) above mean water level (MWL). For 2011 (C), the analysis reveals the existence of two distinct stable attractors at intermediate elevations, with unstable repellors in between. In 2013 (D), only the lower attractor was stable above −0.4 m MWL. Overall, the analyses combined indicate that the 2011 drought triggered a feedback-mediated transition at intermediate elevations from a state of high seagrass cover to a degraded state, as manually illustrated in (C). Solid and dashed gray lines depict stable equilibria and transition thresholds, respectively; the gray arrow indicates the direction of the shift.

Our study, combined with earlier work, highlights the importance of indirect responses of ecosystems to droughts [10]. Desiccation is a well-known stressor in subtropical to tropical intertidal seagrass beds such as Banc d’Arguin where drought and heat waves can cause severe desiccation events, particularly when coinciding with strong winds and neap tides causing prolonged low-tide exposure [15, 24]. Extreme events such as drought, strong winds, and tidal extremes are all predicted to increase in frequency and severity with global warming [36]. Although sea level rise could be expected to mitigate future extreme drought events, expected increases in tidal amplitudes [37] might, depending on local conditions, also further enhance drought stress. Overall, desiccation stress is therefore increasingly considered to become an important threat to intertidal seagrass meadows in warmer regions [15, 16, 24, 38].

Apart from desiccation, there are many other stressors for seagrass beds worldwide that could initiate breakdown of this mutualism, many of which are anthropogenic in origin [13, 39]. For example, eutrophication typically reduces light availability (and thus photosynthesis-driven oxygen release from seagrass roots) due to the higher competitive strength of algae [40], while...
sulfide levels may increase as a result of enhanced input of easily degradable algal and other organic matter [20, 40]. Other examples are siltation events reducing light levels [39], salt stress hampering photosynthesis by seagrasses [37], and increased temperature driving enhanced sulfide production [41]. Due to global change, mutualism breakdown and sulfide toxicity may therefore become a more common phenomenon in seagrass meadows, and thus potentially an important factor in the worldwide decline of seagrass ecosystems [13, 39].

Our results point at a hidden risk of mutualism dependency in marine ecosystems that goes beyond the obligate coral symbiosis: environmental change can disrupt facilitative mutualistic feedbacks, and this may in turn have important consequences for ecosystem functioning and the provided services (e.g., biodiversity enhancement, carbon and nutrient storage, food and water supply, and flood protection) [13, 14, 42]. Indeed, many marine ecosystems with mutualisms, such as coral reefs, seagrass meadows, kelp forest, salt marshes, and mangroves, have declined dramatically due to global change (e.g., global warming, eutrophication, and overfishing) over recent decades [13, 42]. Clearly, the importance of mutualisms for ecosystem functioning, as well as their role in ecosystem losses, needs a better understanding. As mutualism breakdown is likely to become more common in a future governed by global change [4], we suggest that these mechanisms need to be included in marine conservation and restoration approaches.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, three figures, and one table and can be found with this article online at http://dx.doi.org/10.1016/j.cub.2016.02.023.

Supplemental experimental procedures

Study system
Our study was carried out in the tropical intertidal seagrass meadows of Parc National du Banc d’Arguin (PNBA) in Mauritania (19°52.42' N, 16°18.50'W; Figure S1). The intertidal area covers about 500 km² of mudflat dominated by mixed meadows of Zostera noltii, Halodule wrightii and Cymodocea nodosa [S1] that retain consistent aboveground biomass throughout the year [S2] which is typical for seagrasses around the equator [S3]. Characteristic for intertidal mudflats in general, morphology is typified by a gently sloping terrain with a shallow overlying relief (< 10 cm) with depression and elevations alternating at a scale of roughly 10 to 50 meters (Figure S2). This subtle morphology primarily results from sediment trapping by seagrass in interaction with morphodynamics driven by waves, tidal currents, and low-tide dewatering dynamics [S4-S6]. In our system, seagrass meadows accumulate large amounts of silty, organic matter-rich sediment of up to ~1-m thick. The sediment layer between the seagrass roots is inhabited by high densities (up to 3700 ind. m⁻²) of the small (~1 cm) lucinid bivalve *Loripes lucinalis* [S7, S8], which obtains 71% of its carbon nutrition from the obligate mutualism with its gill-inhabiting sulfide-oxidizing bacteria [S9]. Temperature loggers show that mudflat surface temperatures can peak well above 40°C during tidal exposure in this desert climate, causing desiccation that is considered stressful for intertidal seagrass in this system and in general [S10-S13].

Local climate analyses
We obtained daily averaged temperature, dew point temperature, and wind speed data from the coastal weather station in Nouadhibou, which is nearest to our study area (located ~140 km northwards). Dew point depression and water vapor pressure deficit – two direct measures of atmospheric water moisture deficit and thus suitable proxies of atmospheric moisture extraction from land surfaces [S14] – were calculated from the temperature and dew point temperature data. Next, we determined the number of extreme days – defined as days over the 95% percentile – for temperature, wind, dew point depression and vapor pressure deficit for the three warmest months (August to October) over the period 2007-2013. These three months are not only the most stressful for the intertidal seagrass beds with respect to low-tide solar radiation and temperature, but also regarding strain on detoxification by the mutualism as sulfide production is temperature-dependent [S8].

Remote sensing and potential analyses
To investigate seagrass cover changes over time, we used GIS analyses combined with ground observations. We were able to select Landsat 5 and 8 images taken in the warmest months (August-October), at low tide, and with sufficiently low haziness for 2007, 2009, 2011 and 2013 (Table S1). To be able to compare them, we first standardized the images against each other to correct for atmospheric effects, and potential sensor differences. We converted the digital numbers of the spectral bands to top-of-atmosphere reflectance and empirically cross-calibrated reflectance (2009 Landsat image served as baseline), using a linear model fitted to random common ground targets with low and high reflectance (ocean and desert sites, respectively) [S15, S16]. Next, we calculated the Normalized Difference Vegetation Index (NDVI) for each image as a proxy for seagrass cover in the intertidal zone. NDVI (or red NDVI) was calculated from the near-infrared (NIR) and red (RED) spectral bands: (NIR - RED)/(NIR + RED). Analysis of the spatial autocorrelation in each NDVI image using autoregressive AR(p) model estimation revealed that the correlation length (Lc; calculated using 1/e as a correlation threshold) was highest in 2007 with a distance of 112.2 m. To avoid any correlation (and thus potential dependency) between data points, we therefore sampled 239 points from a 250x250 m grid (i.e. at least 2x Lc) for further statistical analysis. Finally, supporting ground observations were carried out by photographing and scoring seagrass cover in 0.5×0.5-m quadrats in two repetitive field surveys in 2009 and 2013 (213 sampling points, Figure S1).

To examine possible feedback-mediated dynamics in our study system, we used potential analysis, a novel statistical method to detect alternative states or ‘basins of attraction’ along an environmental stress gradient [S17-S19]. Potential analysis assumes that variation in NDVI is the result of feedbacks and stochasticity approximated by:

\[
\begin{align*}
    dz &= -U'(z)dt + \sigma dW \\
    (eq. 1)
\end{align*}
\]

where the potential function \(U(z)\) describes deterministic processes (i.e. feedback), and \(dW\) is a Gaussian noise term with intensity \(\sigma\). If distinct ecosystem states exist due to the presence of strong internal feedbacks, transitions between two ‘attractors’ (or stable states) occur rapidly as intermediate states are inherently unstable. The analysis therefore estimates a probability density function \(P_r\) for the variable of interest \(z\) (NDVI in our case) per interval class of an environmental gradient (elevation in our case). Multimodality in the potential function \(U = -\log(P_r)\) in an interval class is an indication of multiple stable attractors: local minima and maxima of \(U\) correspond to stable and unstable attractors, respectively [S19, S20]. Graphically, a system with bimodality would be typically represented by...
a ‘folded sigmoid response’ along the environmental gradient, with two stable attractors separated by an unstable repellor per interval class [S19, S20].

For our analyses, we first binned all 17672 NDVI values of each map in 0.1-m height classes from -0.6 to 0.3 m relative to mean sea level based on a digital elevation map. This map was derived from Landsat images taken at varying tidal levels. Contour lines of the water edge were manually derived from false color images composite using Landsat SWIR, NIR and Green bands and combined into a new map. To assign an absolute elevation to the contour lines, we determined the elevation of each contour line relative to mean sea level using real-time kinematic differential GPS, resulting in a vertical accuracy of approximately two centimeters. Finally, the map was created with in ArcGIS 10 using 3D analyst. For each elevation class we estimated \( P^* \) using a standard Gaussian kernel estimator, smoothed with a moving window (size: 0.025). Local maxima and minima of \( U \) were identified by an automated peak search function.

Field measurements
To investigate the potential link between desiccation stress, seagrass die-off, and mutualism breakdown we compared degraded patches (as die-offs were patchy in nature) with adjacent healthy patches at 8 sites (4 replicates per site) across the study area in October 2012 (Figure S1). At each sampling location, we randomly selected 4 die-off patches – i.e. typified by low cover (<20%), dying seagrass with browning leaves (average cover: 9.4 ±1.0%; mean ±SE; n=32). Next, we compared their general habitat characteristics with adjacent (<10 m) high cover (>60%) healthy areas (average cover: 77.4 ±2.0%), thus resulting in a pairwise approach. To test whether subtle elevation differences on the mudflats (see “Study system”) affected local water run-off and desiccation stress, we first compared relative elevation differences between degrading and healthy patches with a laser to the nearest 1 mm (Spectra Precision Laser LL500) and visually scored the presence or absence (cutoff at 50% cover) of a water film on the sediment surface at low tide (Figures S2B and C). In addition, we measured sediment median grain size and organic matter as indicators of general sediment characteristics. Sediment samples were taken with a small core (ø 1.5 cm) to a depth of 5 cm, weighed immediately after collection and frozen (-10°C). Samples were freeze-dried in the laboratory, after which we determined median grain size using a particle size analyzer with auto sampler (Coulter LS 13 320) and organic matter as loss on ignition (LOI; 5 hrs at 560°C).

Next, we carried out an in-depth investigation at the site of Abelgh Eiznaya (Figure S1) that was selected because it exhibited a level of degradation representative for the study system (Figure 2) and was readily accessible from the research station. In addition to the above variables, we compared lucinid bivalve densities (\( L. \) lucinalis), seagrass biomass (\( Z. \) noltii), and pore water sulfide concentrations (n=8) between degraded and adjacent healthy areas. Lucinids and seagrass were sampled following a standard procedure [S21]: sediment cores (ø: 15 cm) were taken to a depth of 20 cm and then sieved over a 1-mm mesh. Lucinids in the sample were counted in the laboratory.

Statistical analyses
All statistical analyses were conducted using the software program R [S22]. NDVI was analyzed using Generalized Linear Mixed Models (\textit{glm}lm) with a Gaussian distribution with year as a fixed factor, mudflat area (Figure S1) as random factor with Satterthwaite approximation of the degrees of freedom, and Tukey HSD for post-hoc comparisons. Ground observation data were analyzed using the same type of Gaussian \textit{glm}lm with year as a fixed factor and sampling site as random factor (Figure S1).

Differences in sediment height, grain size distribution and organic matter content were tested using one-way ANOVA (\textit{aov}) with location as a random factor. Presence/absence of a water film was fitted with binomial regression (\textit{glm}lm; location as random factor). Sulfide concentrations in the field survey were log-transformed to meet assumptions of normality of residuals. We used a Gaussian-distributed \textit{glm} with patch condition (health/degrading) and sediment depth (0-5 and 5-10 cm) as fixed factors, and sampling point as a random factor to link the upper and lower sediment layer. We used a Generalized Linear Model (\textit{glm}) with Poisson distribution to
compare lucinid counts in degraded and healthy patches 2012. Finally, to compare lucinid densities between patches that remained healthy and patches that became degraded between 2009 and 2013, we used a Poison-distributed glm with year as fixed factor and sampling point as random factor, followed by pairwise post hoc comparisons with Bonferroni correction of significance levels.
